ABSTRACT

Background

Primary malaria prevention on a large scale depends on two vector control interventions: indoor residual spraying (IRS) and insecticide-treated mosquito nets (ITNs). Historically, IRS has reduced malaria transmission in many settings in the world, but the health effects of IRS have never been properly quantified. This is important, and will help compare IRS with other vector control interventions.

Objectives

To quantify the impact of IRS alone, and to compare the relative impacts of IRS and ITNs, on key malarialiological parameters.

Search strategy

We searched the Cochrane Infectious Diseases Group Specialized Register (September 2009), CENTRAL (The Cochrane Library 2009, Issue 3), MEDLINE (1966 to September 2009), EMBASE (1974 to September 2009), LILACS (1982 to September 2009), mRCT (September 2009), reference lists, and conference abstracts. We also contacted researchers in the field, organizations, and manufacturers of insecticides (June 2007).

Selection criteria

Cluster randomized controlled trials (RCTs), controlled before-and-after studies (CBA) and interrupted time series (ITS) of IRS compared to no IRS or ITNs. Studies examining the impact of IRS on special groups not representative of the general population, or using insecticides and dosages not recommended by the World Health Organization (WHO) were excluded.

Data collection and analysis

Two authors independently reviewed trials for inclusion. Two authors extracted data, assessed risk of bias and analysed the data. Where possible, we adjusted confidence intervals (CIs) for clustering. Studies were grouped into those comparing IRS with no IRS, and IRS compared with ITNs, and then stratified by malaria endemicity.
Main results

IRS versus no IRS

**Stable malaria (entomological inoculation rate (EIR) > 1):** In one RCT in Tanzania IRS reduced re-infection with malaria parasites detected by active surveillance in children following treatment; protective efficacy (PE) 54%. In the same setting, malaria case incidence assessed by passive surveillance was marginally reduced in children aged one to five years; PE 14%, but not in children older than five years (PE -2%). In the IRS group, malaria prevalence was slightly lower but this was not significant (PE 6%), but mean haemoglobin was higher (mean difference 0.85 g/dL).

In one CBA trial in Nigeria, IRS showed protection against malaria prevalence during the wet season (PE 26%; 95% CI 20 to 32%) but not in the dry season (PE 6%; 95% CI -4 to 15%). In one ITS in Mozambique, the prevalence was reduced substantially over a period of 7 years (from 60 to 65% prevalence to 4 to 8% prevalence; the weighted PE before-after was 74% (95% CI 72 to 76%).

**Unstable malaria (EIR < 1):** In two RCTs, IRS reduced the incidence rate of all malaria infections; PE 31% in India, and 88% (95% CI 69 to 96%) in Pakistan. By malaria species, IRS also reduced the incidence of *P. falciparum* (PE 93%, 95% CI 61 to 98% in Pakistan) and *P. vivax* (PE 79%, 95% CI 45 to 90% in Pakistan); There were similar impacts on malaria prevalence for any infection; PE 76% in Pakistan; PE 28% in India. When looking separately by parasite species, for *P. falciparum* there was a PE of 92% in Pakistan and 34% in India; for *P. vivax* there was a PE of 68% in Pakistan and no impact demonstrated in India (PE of -2%).

IRS versus Insecticide Treated Nets (ITNs)

**Stable malaria (EIR > 1):** Only one RCT was done in an area of stable transmission (in Tanzania). When comparing parasitological re-infection by active surveillance after treatment in short-term cohorts, ITNs appeared better, but it was likely not to be significant as the unadjusted CIs approached 1 (risk ratio IRS:ITN = 1.22). When the incidence of malaria episodes was measured by passive case detection, no difference was found in children aged one to five years (risk ratio = 0.88, direction in favour of IRS). No difference was found for malaria prevalence or haemoglobin.

**Unstable malaria (EIR < 1):** Two studies; for incidence and prevalence, the malaria rates were higher in the IRS group compared to the ITN group in one study. Malaria incidence was higher in the IRS arm in India (risk ratio IRS:ITN = 1.48) and in South Africa (risk ratio 1.34 but the cluster unadjusted CIs included 1). For malaria prevalence, ITNs appeared to give better protection against any infection compared to IRS in India (risk ratio IRS:ITN = 1.70) and also for both *P. falciparum* (risk ratio IRS:ITN = 1.78) and *P. vivax* (risk ratio IRS:ITN = 1.37).

Authors’ conclusions

Historical and programme documentation has clearly established the impact of IRS. However, the number of high-quality trials are too few to quantify the size of effect in different transmission settings. The evidence from randomized comparisons of IRS versus no IRS confirms that IRS reduces malaria incidence in unstable malaria settings, but randomized trial data from stable malaria settings is very limited. Some limited data suggest that ITN give better protection than IRS in unstable areas, but more trials are needed to compare the effects of ITNs with IRS, as well as to quantify their combined effects.

**PLAIN LANGUAGE SUMMARY**

Indoor residual spraying for preventing malaria

Plain language summary pending.

**BACKGROUND**

There were an estimated 247 million malaria cases among 3.3 billion people at risk in 2006, causing nearly one million deaths, mostly of children under five years. One hundred and nine countries were endemic for malaria in 2008, 45 within the WHO...
African region (WHO 2008). Ninety per cent of all malaria cases occur in sub-Saharan Africa, in areas of stable endemic transmission, and around 20% of all deaths in children have been attributed directly to malaria (Snow 1999). The disease causes widespread premature death and suffering, imposes financial hardship on poor households, and holds back economic growth and improvements in living standards. The rapid spread of resistance first to chloroquine and now to sulfadoxine-pyrimethamine has greatly increased the cost and difficulty of malaria case management, particularly in Africa (RBM 2005). Estimates have suggested that malaria costs the African countries US$12 billion annually and may considerably retard economic development (Sachs 2002).

Primary prevention of malaria is essentially achieved through two main vector control interventions: indoor (house) residual insecticide spraying (IRS); and insecticide-treated (mosquito) nets (ITNs). The health effects of ITNs have been comprehensively summarized in two Cochrane Reviews, one for general populations (Lengeler 2004) and one for pregnant women (Gamble 2006).

IRS has a long and distinguished history in malaria control. Using mainly dichloro-diphenyl-trichloroethane (DDT), malaria was eliminated or greatly reduced as a public health problem in Asia, Russia, Europe, and Latin America (Schiff 2002; Lengeler 2003; Roberts 2004). IRS continues to be used in many parts of the world, with the services provided by the public health system or by a commercial company (usually for the benefit of its employees). There is no IRS programme known to us in which beneficiaries were expected to contribute financially.

A historical review of IRS in Southern Africa investigated the malaria situation before and after the introduction of IRS in South Africa, Swaziland, Namibia, Zimbabwe, and Mozambique, where it continues to protect 13 million people (Mabaso 2004). After the implementation of control operations, spectacular reductions in malaria parameters and vector densities were recorded, and in certain instances the intervention led to local elimination. Another historical paper reviewed the health impacts of 36 successful IRS programmes in 19 countries throughout sub-Saharan Africa (Kouznetsov 1977). The analyses compared parasite rates and other malariological outcomes before and after the operation in each of the five major eco-epidemiological zones and demonstrated substantial epidemiological benefits. Unfortunately, most of these studies simply documented time trends of malaria parameters with no appropriate control groups. This is also the case for the most recent programme impact assessments (Sharp 2002; Tseng 2008; Teklehaimanot 2009; Kleinschmidt 2009). Hence, while there is no doubt that IRS reduces malaria transmission and improves health outcomes, assessments up to the present day do not allow us to quantify the health effects.

IRS is thought to operate both through repelling mosquitoes from entering houses and by killing female mosquitoes that are resting inside houses after having taken a blood meal. This implies that IRS is most effective against mosquito species that are resting indoors (so called endophilic mosquitoes). Whereas ITNs show a high degree of personal protection, IRS relies largely on a vectorial mass effect: the increased mortality of adult vectors mostly following feeding leads to a reduction in transmission. Spraying needs to be carried out between once and three times per year; the timing depending on the insecticide and the seasonality of transmission in a given setting. Reviewing the advantages and disadvantages of each insecticide is beyond the scope of this review and can be found among other in Najera 2001.

IRS has the advantage of being able to make use of a much wider range of insecticide products in comparison to ITNs, for which pyrethroids are the only class of insecticide currently used. The World Health Organization (WHO) recommends a number of insecticides for individual residual spraying: DDT wettable powder (WP); malathion WP; fenitrothion WP; pirimiphos-methyl WP and emulsifiable concentrate (EC); bendiocarb WP; propoxur WP; alpha-cypermethrin WP & suspension concentrate (SC); cyfluthrin WP; deltamethrin WP; etofenprox WP; lambda-cyhalothrin capsule suspension (CS) and WP (WHOPESE 2007). This extended range of insecticides has important benefits for the management of insecticide resistance and hence the long-term sustainability of vector control (pyrethroid resistance has already been reported in many parts of tropical Africa and other parts of the world among populations of the major malaria vectors). The potentially adverse effects of insecticides used for IRS, especially DDT, is an important issue but one that is beyond the scope of this review.

Insecticide spraying is often done on a very large scale in order to maximize the mass effect of the insecticide; thus randomized controlled trial (RCT) designs may not always be feasible. However, controlled before-and-after studies (CBA) are clearly feasible, as are interrupted time series (ITS). We plan to include these three study designs while excluding simple pre-test and post-test studies with no concurrent controls, as the many potential biases make interpretation a problem. In all identified studies, allocation is expected to be by clusters rather than by individuals, since IRS is thought to be only effective if a large proportion of the population is protected.

Two reviews have outlined the cost and health effects of IRS (Curtis 2001; Lengeler 2003) including a comparison of IRS against ITNs, but neither was conducted systematically or assessed the methodological quality of the included studies. Yukich 2008 presented standardized cost and cost-effectiveness assessments for the major ITN distribution models as well as for two IRS programmes in Southern Africa.

Here we aim to quantify the health benefits of IRS and to compare how IRS and ITNs differ in their ability to prevent ill-health from malaria.
OBJECTIVES

To quantify the impact of IRS alone, and to compare the relative impacts of IRS and ITNs, on key malarious parameters.

METHODS

Criteria for considering studies for this review

Types of studies

1. RCTs and quasi-RCTs, randomized by cluster (cluster RCTs) and with three or more units per arm Bennett 2002; because of the mode of action of IRS (relying on a mass effect) we did not expect to find trials with individual randomization.

2. Controlled before-and-after studies with (1) two or more units per arm, (2) a contemporaneous control group, (3) monitoring of at least one transmission season before and after the intervention and (4) at least 60% coverage in the intervention arm.

3. Interrupted time series, with (1) a clearly defined point in time when the intervention occurred, (2) monitoring of at least two transmission seasons before and after the intervention and (3) at least 60% coverage in the intervention arm.

Types of participants

Children and adults living in rural and urban malarious areas. Excluded: studies examining the impact of IRS on soldiers, refugees, industrial workers and other special groups not representative of the general population.

Types of outcome measures

Before the start of the review the following standardized outcomes were specified:

- All cause child mortality: children aged < 10 years, mortality determined by a prospective demographic surveillance system.
- Severe disease: site-specific definitions based on the WHO guidelines WHO 2000. The definition includes demonstration of parasitaemia. Cerebral malaria is defined as coma or prostration and/or multiple seizures. The cut-off for severe, life-threatening anaemia is set at 5.1 g/L.
- Uncomplicated clinical malaria episodes: site-specific definitions, including fever, usually with parasitological confirmation, detected passively or actively. The case definition must be similar in all trial arms for the trial to be included in the analysis.
- Incidence of re-infections (after treatment): incidence rate of parasitaemia following radical cure; done with cohorts of children over 8 weeks.
- Parasite prevalence: obtained using a site-specific method for estimating parasitaemia, usually thick and/or thin blood smears.
- High density malaria prevalence: same as for parasite prevalence but with a site-specific parasitological cut-off.
- Haemoglobin levels (g/dL).
- Standard anthropometric measures: weight-for-age, height-for-age, weight-for-height, skinfold thickness, and/or mid-upper arm circumference.
- Splenomegaly: measured using Hackett's scale from 1 to 5.

Search methods for identification of studies

We attempted to identify all relevant studies regardless of language or publication status (published, unpublished, in press, and in progress). For details see Table 1.

<sup>a</sup>Cochrane Infectious Diseases Group Specialized Register  <sup>b</sup>Upper case: MeSH or EMTREE heading; Lower case: free text term

**Databases**

On 16 September 2009 we searched the following databases using the search terms and strategy described in Table 1: Cochrane Infectious Diseases Group Specialized Register; Cochrane Central Register of Controlled Trials (CENTRAL) as published in The Cochrane Library; MEDLINE; EMBASE; and LILACS. We also searched the metaRegister of Controlled Trials (mRCT) using ‘insecticide$’ and ‘malaria’ as search terms.

**Agencies and manufacturers**

We contacted the following agencies, which have funded malaria control studies, for unpublished and ongoing trials: World Bank; UNICEF; World Health Organization; PAHO; and USAID. We also contacted the following manufacturers of insecticides: Bayer; BASF; Sumitomo; and Syngenta (June-July 2007). In June 2007 we also searched the US Armed Forces Pest Management Board web site for relevant trials, as well as all other sources that we identified in the process of the search.

**Reference lists**

We checked the reference lists of all studies identified by the above methods.

**Data collection and analysis**

1. **Study selection**

BP screened the results of the search strategy for potentially relevant studies and retrieved full articles. BP and FT independently assessed all identified studies for inclusion in the review, using an eligibility form based on the inclusion criteria. We scrutinized each report to avoid study duplication. We attempted to contact the study authors for clarification if it was unclear whether a study met the inclusion criteria or if there were issues with the study design. CL was asked to resolve any differences in opinion. We explain below the reasons for excluding studies (“Characteristics of excluded studies”).
2. Assessment of methodological quality
BP/FT and CI independently evaluated the methodological quality of each included study. We attempted to contact the study authors if key information was missing or unclear, and resolved any disagreements through discussion.

2.1. RCTs
BP assessed the risk of bias of each included trial using The Cochrane Collaboration’s risk of bias tool (Higgins 2008). We followed the guidance tool to make judgements on the risk of bias in six domains: sequence generation; allocation concealment; blinding (of participants, personnel, and outcome assessors); incomplete outcome data; selective outcome reporting; and other sources of bias. We categorized these judgements as ‘yes’ (low risk of bias), ‘no’ (high risk of bias), or ‘unclear’.

2.2. Controlled before-and-after studies
We followed a strategy published elsewhere (Adinarayanan 2007); BP and FT independently assessed the quality of the included CBA study using a variety of criteria that we considered important and had specified a priori. These included: high intervention coverage in the community of interest (defined as at least 60% IRS coverage), presence of some type of comparison group with no intervention, reporting of outcomes for the entire community. We also attempted to identify concurrent control activities carried out at the same time or just before the IRS intervention by screening the primary study report and other relevant literature.

2.3. Interrupted time series
We used the criteria published elsewhere (EPOC 2002) to assess the study quality of the one included study. Criteria included protection against secular changes, sufficient data points to enable reliable statistical inference, protection against detection bias, and completeness of the data set. We also attempted to identify concurrent control activities carried out at the same time or just before the IRS intervention by screening the primary study report and other relevant literature.

3. Data extraction
BP independently extracted the data from each study into standardized data extraction forms. Again, we attempted to contact the corresponding author in any case of unclear or missing data.

3.1. RCTs
We extracted data according to the intention-to-treat principle: if any individual allocated to a treatment group was analysed as if the person had effectively received the intervention. If there was discrepancy between the number of units/participants randomized and the number of units/participants analysed we calculated the percentage losses to follow-up in each group and reported this information. In trials that compared ITNs with IRS, we assessed the differences in coverage between the different groups and presented this information in a table.

Cluster RCTs: Where results have been adjusted for clustering, we extracted the point estimate and the 95% confidence interval (CI). If the results were not adjusted for clustering, where possible we extracted outcome data as for individual RCTs and corrected the data in the analysis. We always recorded the number of clusters, the average size of clusters, and the unit of randomizations (eg household, village or other). The statistical methods used to analyse the trials are described below in section 4.1.

3.2. Controlled before-and-after studies
We extracted data using the same methods as for the RCTs, but we added information on the comparability of baseline characteristics and the time period of data collection.

3.3. Interrupted time series
We extracted data using the same methods as for the RCTs, but we added information on the comparability of baseline characteristics and additional information relating to the assessments made before and after the initiation of the intervention, using the approach recommended by EPOC 2002.

4. Data analysis

4.1. Cluster RCT
We had planned to meta-analyse the data from RCTs using Review Manager 5. However, the number of the trials was too low to meaningfully do such a meta-analysis. Hence we have only presented a narrative or tabulated summary of all study data. All results are either presented as rates/proportions or as Risk Ratios (RR). From the RR the protective efficacy (PE; expressing the percentage reduction in an outcome) was derived using the formula: $PE = (1 - RR) \times 100$.

Cluster RCTs with two or three arms and at least three clusters per arm were used for the comparisons of IRS versus no intervention or IRS versus ITNs. Three clusters per arm is considered a minimum (1) to minimize the risk of imbalances between groups, and (2) to allow appropriate statistical analysis (Bennett 2002). The two other study designs (CBA and ITS) were used only for the comparison of IRS versus no intervention.

Cluster trials require a more complex analysis than that for individual RCTs (Hayes 2000). Observations on participants in the same cluster tend to be correlated and that intra-cluster variation must be accounted for during the analysis. If this correlation is
ignored in the analysis the measure of effect remains a valid estimate but the associated variance of the estimate would be underestimated, leading to unduly narrow CIs.

For dichotomous outcomes expressed as risk, the results can be adjusted for clustering by multiplying the standard errors of the estimates by the square root of the design effect, where the design effect is calculated as $DEff=1+(m-1)\cdot ICC$. This requires information such as the average cluster size (m) and the intra-cluster correlation coefficient (ICC). Unfortunately, the ICC was never reported by trial authors and hence cluster-adjustment was not always possible post-hoc. When the unadjusted CIs did not demonstrate a significant difference, then this is indicated.

For dichotomous outcomes expressed as rates, we applied the methods described in (Bennett 2002) using a rate ratio calculated from the mean incidence rates for each treatment group. In the case of the study by Misra 1999 the authors used a geometric mean of the incidence rates and we applied the method described by Bennett 2002 using a rate ratio based on the geometric mean incidence rates for the outcomes "P. vivax and P. falciparum combined".

**Heterogeneity:** With enough trials we would have assessed heterogeneity by (1) inspecting the forest plots to detect overlapping CIs, (2) applying the Chi² test with a P value of 0.10 indicating statistical significance, and (3) implementing the I² statistic with a value of 50% denoting moderate levels of heterogeneity. However, the number of trials was so low that combining trials was not possible. We stratified the presentation of the results into two groups on the basis of the entomological inoculation rate (EIR; number of infected bites per person per day) where < 1 was considered unstable malaria transmission, while settings with an EIR > 1 were considered to have stable transmission. A stratification on the basis of the main types of vectors, types of insecticides and other important factors was not possible because of the low number of trials. Where possible the analysis was stratified by parasite species (P. falciparum and P. vivax). Finally, consideration was given to the fact that in some areas the vector control activities have gone on for many years before the reported study, while in some other situations the investigated study introduced the vector control activities. While we have at present no way to assess the effect of this difference, areas having had vector control for a long time are clearly different from areas with no previous activities in many different aspects (entomological and human health parameters).

**Sensitivity analysis:** There weren’t sufficient trials to conduct a sensitivity analysis to investigate the robustness of the results.

### 4.2. Controlled before-and-after studies

We analysed the study in the same manner as RCTs and presented the results in tables.

### 4.3. Interrupted time series

We analysed the study in the same manner as RCTs and presented the results in tables.

### RESULTS

**Description of studies**

See: Characteristics of included studies; Characteristics of excluded studies; Characteristics of studies awaiting classification.

**Results of the search**

We identified 134 potentially relevant studies. Of these we excluded 128 studies (for details of reasons see below and “Characteristics of excluded studies”). The remaining six studies met all the inclusion criteria. These trials are described below (for details see also “Characteristics of included studies”).

**Included studies**

**Trial design and location**

Out of the six included studies, four were RCTs (Curtis 1998; Misra 1999; Mnzava 2001; Rowland 2000), and in all of these the allocation was by cluster (by villages, geographical blocks and sectors comprising several villages). One study was a CBA (Molineaux 1980) and one was an ITS (Sharp 2007).

Four trials were conducted in sub-Saharan Africa: Tanzania (Curtis 1998), South Africa (Mnzava 2001), Nigeria (Molineaux 1980) and Mozambique (Sharp 2007); one was conducted in Pakistan (Rowland 2000) and one in India (Misra 1999).

Three trials were in areas with stable transmission (EIR>1) and three in areas with unstable transmission (EIR<1) (Table 2).

c Within other areas in Kwa-Zulu Natal, A. funestus was shown to be resistant to deltamethrin. However, there was no evidence that pyrethroid-resistant A. funestus were present in the area during the reported study
d IEC: Information, Education and Communication

Participants
The trials included either all ages (Misra 1999; Mnzava 2001; Molineaux 1980; Sharp 2007 for first year) or specific age groups (different groupings among children aged one to 15 years) (Curtis 1998; Rowland 2000; Sharp 2007 for subsequent years).

Intervention
RCT:
One trial compared the impact of IRS versus the provision of ITNs to all inhabitants (Mnzava 2001). Two trials had three arms and compared the impact of IRS to the impact of ITN and to an untreated control zone (Curtis 1998; Misra 1999). One trial studied the impact of IRS in comparison to a control area without any intervention (Rowland 2000). For IRS, all studies used pyrethroids as insecticide. Two of them used deltamethrin (dosage = 20 mg/m²), and the two others lambdacyhalothrin (30 mg/m²) and alphacypermethrin (25 mg/m²). Since there is no evidence to suggest that there is a difference between these insecticides in terms of impact they were grouped for analysis. Two trials did not specifically report the spray coverage (Mnzava 2001; Curtis 1998) but oral communication from the investigators suggested coverage was “high”; for the other two (Misra 1999; Rowland 2000) coverage ranged from 92.2% to 96%. For treating ITNs, lambdacyhalothrin (10 mg/m² and 20 mg/m²), deltamethrin (25 mg/m²) and permethrin (200 mg/m²) were used. Again, available evidence (Lengeler 2004) does not suggest any difference in impact between these three pyrethroids. Coverage rates with ITNs ranged in two trials from 85.4% to 100% (Misra 1999; Mnzava 2001), while...
one trial didn’t report coverage (Curtis 1998) but it was “high” since nets were given for free to the whole population (Curtis C. personal communication).

In two of the three trials comparing IRS with ITNs (Mnzava 2001) IRS was done in the ITN areas before these were distributed. In the study area in KwaZulu-Natal there is a long history of IRS (around 50 years). Within the study area, all the houses in the ITN arm were sprayed in September 1996 before distributing the ITNs in January 1997. In subsequent years, house spraying was deliberately withdrawn in blocks with bed nets. In India (Misra 1999) there was a similar situation because of the long history of IRS in the study area, which started in 1953. IRS is nowadays a mainstay of malaria control in the study area.

CBA:
The impact of IRS was compared to a control area without any intervention (Molineaux 1980). Propoxur (2 g/m²) was used as insecticide. The spray coverage ranged from 74% to 100%. There was no history of IRS in the area before this trial.

ITS:
In the study of Sharp 2007 the change over time due to IRS was examined over the time period of two years before and five years after the introduction of IRS. The insecticide used was bendiocarb (400 mg/m²) and no usage coverage was mentioned. No history of IRS has been reported within the area before this study. Some additional characteristics of the trials are given in Table 2.

Outcomes
Prevalence and incidence of malaria infections were the main outcomes that we could assess. See Table 3 for details.

Five studies looked at the prevalence rates of parasitaemia. Of these, two RCTs (Misra 1999; Rowland 2000) were conducted in unstable malaria settings and one RCT (Curtis 1998), one ITS (Sharp 2007) and one CBA (Molineaux 1980) in stable malaria settings.

The incidence rate of malaria infections (local case definitions) was assessed in four studies. Of these, three RCTs were conducted in unstable malaria settings (Rowland 2000; Misra 1999; Mnzava 2001) and one RCT (Curtis 1998) in a stable malaria setting. In one setting (Curtis 1998) the authors also reported incidence of re-infections in multiple short-term cohorts of children (seven to eight weeks) following radical cure.

Impact on infant parasitological conversion rates was measured by Molineaux 1980, while anaemia as additional outcomes was collected in a stable malaria settings by Curtis 1998.

Infant mortality rates were measured by Molineaux 1980 but unfortunately not in a suitable control area, and hence this outcome could not be used.

**Excluded studies**

One hundred and twenty-eight studies were excluded due to the following reasons (for details see table "Characteristics of excluded studies"):

- 40 did not have enough units/arm (minimum required: RCT: 3 clusters per arm, CBA: 2 clusters per arm)
- 22 did not have control sites which were comparable with the intervention sites
- 8 used an insecticide or a dosage not recommended by WHO
- 12 were only reviews or conference abstracts and did not provide enough data
- 28 were ITS which did not provide enough data for pre- or post-intervention assessment
- 14 were ITS using a mix of interventions
- 2 trials did not collect contemporaneous data for the control and intervention sites
- 5 measured non-eligible outcomes
- 1 trial included refugees as study participants
- 2 studies used a non-experimental approach (modelling)
- 1 RCT had a randomized allocation of the intervention that was not acceptable
- 2 studies had an IRS coverage under 60%
- 1 trial experienced a population movement of over 10%
- 1 trial sprayed with DDT in an area with documented DDT resistant Anopheles.

**Risk of bias in included studies**

For an overview of the risk of bias see Figure 1 and Figure 2.
Figure 2. Methodological quality summary: review authors’ judgements about each methodological quality item for each included study.

**Allocation**

Two of the four RCTs (Misra 1999; Mnzava 2001) generated allocation sequences by public drawing/tossing of coins. The risk of bias with these methods is low and allocation concealment is ensured by the fact that the allocation was made in public. The remaining two RCTs (Curtis 1998; Rowland 2000) don’t specify how the randomization was done and how allocation concealment was secured. Therefore the risk for bias can’t be assessed.

**Blinding**

Blinding is neither possible for IRS nor for ITNs and this criteria should therefore not be considered for assessing study quality. Given the type of interventions and the nature of the outcomes, the risk of bias resulting from the absence of blinding is judged as low.

**Incomplete outcome data**

- Curtis 1998
- Misra 1999
- Mnzava 2001
- Molineaux 1980
- Rowland 2000
- Sharp 2007
Two of the six included trials (Misra 1999; Molineaux 1980) reported changes in the number of participants over time. In one trial (Misra 1999) the losses to follow-up were under 10% and therefore the risk of bias was considered to be low. In one other trial (Molineaux 1980), there was a large migration with 15% to 20% of the population changing per year. The migration was described in detail within the study. Furthermore, the study did an analysis to check for the risk of bias due to the population movements and it was considered to be low. The other trials didn’t report on losses to follow-up. Since they were calculating “person-time-at-risk” as denominators the rates were accurate but the risk of selection bias over time could not be estimated.

Selective reporting

None of the studies contained enough information to permit a reliable judgment of the risk of this type of bias.

Other potential sources of bias

In one trial (ITS, Sharp 2007) all age categories were sampled in December 1999, but subsequent surveys were confined to children two to 14 years of age. Fortunately the authors gave details by age in the 1999 survey and hence this change did not matter. Mnzava 2001 compared IRS versus ITNs. However, houses in bed net blocks had already been sprayed by the time the nets were distributed in 2007. Even though there was immediately an effort by investigators to re-plaster these houses to cover the insecticide on the walls, the effect of ITNs might be overestimated due to the dual protection for a limited time. In subsequent years, house spraying was deliberately withdrawn in blocks with bed nets. In the study of Misra 1999 a high incidence of plastering mud on the walls of houses was reported (Misra 1999). This most likely reduced the effectiveness of IRS and hence underestimated its real effect. Unfortunately the authors don’t provide detailed data on the replastering to allow a judgment on its impact.

Effects of interventions

Comparison 1: IRS versus no IRS

Stable malaria (EIR > 1)

Incidence of infection: Only one RCT assessed the impact of IRS against no IRS in a stable malaria setting: Curtis 1998 compared the impact of IRS with lambda-cyhalothrin versus a control group with no intervention in a highly endemic malaria setting in Tanzania. In that trial IRS was shown to be effective in protecting children aged less than five years from reinfection with malaria parasites following radical cure: over an 11 month period, the PE was 54% (Table 4). In the same setting, malaria case incidence assessed by passive surveillance was probably reduced in children aged one to five years: PE 14%, but not in children older than five years: PE -2% (Table 4).

</table>
One CBA in Nigeria (Molineaux 1980) and one ITS in Mozambique (Sharp 2007) were also conducted in stable malaria settings but neither of these two trials measured incidence rates. However, Molineaux 1980 measured infant parasitological conversion rates and found a slight reduction in the areas with IRS compared to areas without (Table 5).

Prevalence of infection: For malaria prevalence no difference was seen between the IRS and control groups in the RCT of Curtis 1998: PE 6% (Table 4). In both Molineaux 1980 and Sharp 2007 the malaria prevalence was reduced where IRS was applied. However, Molineaux 1980 found a significant difference only for the prevalence rates during the wet season in which IRS showed a PE of 26% (95% CI 20 to 32%), while the PE in the dry season was only 6% (95% CI -4 to 15%) (Table 6). In Mozambique (Sharp 2007), the prevalence rate dropped from 60 to 65% before the spraying to 4% in 2005 (Table 7). On average the prevalence rate was 62% before spraying (939/1515) and 16% (638/3960) after, a reduction of 74%.

<sup>a</sup> MD: Mean Difference, one year after start of implementation (4th quarter 1996).  
<sup>b</sup> ITN group
Infant mortality rate: Molineaux 1980 measured infant mortality rates (IMR) but unfortunately without measuring it in a control area. They then derived evidence of impact from the close correlation between reduced infant parasitological conversion rates and IMR. It is unfortunate that because of this limitation these unique mortality data could not be used in our analysis.

Unstable malaria (EIR < 1)

Incidence of infection: IRS was shown to significantly reduce the incidence of malaria infections with a PE of 31% in India (Misra 1999) and 88% (95% CI 69 to 96%) in Pakistan (Rowland 2000; Table 9). IRS also reduced the incidence of malaria in a similar way when looking separately at *P. falciparum* (PE 93%, 95% CI 61 to 98% in Pakistan) and *P. vivax* (PE 79%, 95% CI 45 to 90% in Pakistan).

*a* Not adjusted for clustering

*b* Adjusted for matching, but not for clustering

Prevalence of infection: only one trial in India (Misra 1999) compared IRS to ITNs for this outcome. ITNs appeared to give a better protection against any infection compared to IRS: risk ratio IRS:ITN = 1.70, but CIs were not adjusted (Table 11). The point estimates of this apparent difference were similar for *P. falciparum* infections: risk ratio IRS:ITN 1.78 and slightly lower for *P. vivax* infections: risk ratio 1.37.

India (Misra 1999) and KwaZulu Natal (Mnzava 2001) have a long history of IRS with 50 years and 60 years of spraying, respectively. The effect such a long pre-trial spraying period had on the measures of impact, especially for the ITN arm, could not be explored in the present analysis.
**DISCUSSION**

Since the 1950s, IRS has been used widely in many areas of the world, especially in Asia, Latin America and Southern Africa. IRS with DDT and other insecticides has been one of the main interventions leading to the elimination of malaria in about half of the world's regions, for example in much of southern Europe, North America, Japan, Central Asia and Latin America and it is still being widely used (Lengeler 2003; WHO 2008). Very low levels of malaria transmission have also been achieved and maintained in countries as different as India, Tadjikistan and Colombia. Hence the effectiveness of this intervention is beyond doubt. Unfortunately, the epidemiological effect has never been quantified properly, so that a comparison with other malaria control interventions, for example with ITNs, is impossible. As a result, an accurate comparative cost-effectiveness assessment is also impossible.

With the exception of Southern Africa (South Africa, Namibia, Botswana, Swaziland, and Zimbabwe) and the Ethiopian and Madagascar highlands, the implementation of IRS in the highly endemic areas of sub-Saharan Africa has been restricted in geographical extent and usually only undertaken for a limited time period. Recently, IRS was introduced in a number of African countries - southern Mozambique, Equatorial Guinea, Zambia, Ghana, Sao Tome, and Zanzibar. There is a new interest for IRS since 2007 in the wake of the United States President's Malaria Initiative (PMI). For many of the other endemic countries of sub-Saharan Africa, vector control has been scaled up since 2000 onwards through the increased deployment of ITNs. In this context, two important questions have emerged: (1) what are the comparative advantages, including feasibility, cost and impact of ITNs and IRS; and (2) is there any benefit in combining both IRS and ITNs together to increase impact, especially in view of the goal of malaria elimination declared in 2007?

While there are now good data on comparative feasibility and cost (see review by Yukich 2008), the present review confirms the paucity of high-quality evidence in the comparative assessment of health impact. There are too few high-quality randomized controlled studies on the health effects of IRS, and not enough geographical coverage. Only six out of 134 identified studies met our inclusion criteria (four RCTs, one CBA and one ITS) and not all key malariological outcomes were addressed within these studies. Unfortunately, none of the studies investigated the potential of IRS for reducing child mortality rates. In some ways, these results are not entirely surprising considering the fact that (1) IRS started to be implemented on a large scale after the invention of DDT in 1943 (and hence before the first RCT conducted in 1948), and (2) IRS with DDT was outstanding in its health effects from the start, therefore giving no strong rationale for public health officials in the 1950s and 1960s to formally test its effects.

Currently, our evidence on the question of the impact of the combination of IRS with ITNs is also very limited. A recent review (Kleinschmidt 2009) has suggested some additive effects but the evidence only stems from descriptive studies, and properly conducted RCTs are urgently required.

Overall, the formal quality of the six included trials was considered to be satisfactory. Two of the four RCTs used appropriate methods for sequence generation and allocation concealment, whereas the other two trials didn't mention their procedure. However, given the nature of the intervention and the fact that it was allocated by cluster, this is unlikely to have led to bias in the results. Due to the nature of the intervention, blinding was not possible, but no risk of bias was expected because of this.

A much bigger issue for the validity of the results is the implementation of the interventions. In three (Misra 1999; Mnzava 2001; Rowland 2000) of the four RCTs, the control and/or ITN arms of the trials had a long previous history of IRS, and spraying was simply suspended in the ITN arm for the duration of the trial. Obviously, the entomological baseline situation was not any more that of an untouched area. In addition, insecticide was sprayed shortly before ITN distribution in the ITN arms in India and Tanzania. Despite the best efforts by investigators to minimize the effects of this by re-plastering the walls, that interference is still likely to have had an independent effect on the outcomes. Unfortunately, it is impossible to quantify these effects.

Only two different classes of insecticides (carbamates and pyrethroids) were used in the reviewed trials, to which the mosquitoes were fully susceptible in all settings. Insecticide resistance is an obvious threat to the effectiveness of IRS. However, unlike 50 years ago, when DDT was the only insecticide on hand, there are now 12 different insecticides within four different chemical classes available for IRS. This gives the possibility to alternate the insecticides and to switch to other insecticides in case of emerging resistance. This is a clear advantage over ITNs, for which only one class of insecticide is available (pyrethroids). On the other hand, ITNs still offer a physical barrier to the vector, even if the insecticide doesn't work anymore, whereas for IRS the protection through the insecticide will be strongly reduced.

The low number of trials unfortunately prevented us from carrying out any form of sub-group analysis, which would have included the impact of different types of insecticides, the length of the transmission season, the type of vectorial systems and other factors thought to be important.

The four included randomized controlled trials were distributed between Asia and sub-Saharan Africa. Only one RCT was done in a stable malaria setting (EIR >1, Curtis 1998). Three RCTs were done in unstable malaria settings (EIR <1). Two of them were in Asia (Misra 1999 (India); Rowland 2000 (Pakistan)) and one in Africa (Mnzava 2001 (South Africa)).

Comparing IRS to no IRS in stable settings, in the study in Tanzania (Curtis 1998) the risk for children under six to get re-in-

fected with malaria parasites after radical cure was reduced approximately by half (PE: 54%), an indication that IRS reduced malaria transmission. Paradoxically, no changes was observed in malaria incidence rates when cases were detected by passive surveillance (without initial parasite clearance). Possibly, the clearance of all infections with an effective antimalarial (chlorproguanil-dapsone), something not usually done in vector control trials, had an additional independent effect. Hence, the generalization of these results to other malaria endemic areas needs to be questioned.

For IRS versus no IRS in unstable areas, the trials from India and Pakistan both showed that IRS protected all age groups and for both *P. falciparum* and *P. vivax* in these settings from malaria infections.

When comparing IRS versus ITNs, in the one trial in a stable area Curtis 1998 there was a trend towards ITNs having a greater PE than IRS on incidence after radical cure but the unadjusted CIs approached 1 (risk ratio IRS:ITN = 1.22). However, when the incidence was measured by passive case detection, there was a slight but non significant difference in favour of IRS in children aged one to five years (risk ratio = 0.88). No difference was found for malaria prevalence or haemoglobin.

ITN appeared to be more protective than IRS in unstable areas. For malaria prevalence, ITNs appeared to give better protection against any infection compared to IRS in India.

The results of this review do not reconcile well with the impressive historical reductions of malaria in many areas of the world following the introduction of IRS. Among these areas were also a number of high transmission areas in sub-Saharan Africa (Koznetsov 1977; Mabaso 2004). In part this discrepancy could be explained by the fact that programmes were conducted on a much larger scale and for a much longer time period than trials, with a resulting better impact. Hence, the lack of positive evidence from formal trials should not, in the case of IRS, be interpreted as a lack of effect of the intervention. Rather, it is the consequence of a lack of high-quality and long-duration trials on a large scale done in areas not previously under vector control. As a result, the main aim of the review (to quantify the health effects of IRS) could not be achieved and our major conclusion is that high-quality evidence from RCTs is still required. For obvious ethical reasons a control group without vector control intervention is not acceptable any more and such trials should therefore have at least two arms, an IRS arm and an ITN arm. Given the importance of also assessing the combined effect of IRS and ITNs, a third arm with both interventions together would be highly desirable.

**The current evidence is insufficient to quantify properly the effect of IRS in high transmission settings although it seems clear that IRS leads to health benefits.**

**Available good quality evidence confirms that IRS works in reducing malaria in unstable malaria settings.**

**At present, a quantitative epidemiological comparison between IRS and ITNs is not possible.**

**No trial investigated the effect of IRS in reducing (child) mortality.**

**There is insufficient epidemiological evidence to assess the effect of other determinants of impact, such as the insecticide class used for IRS, the type of transmission, the dominant vector species and socio-cultural determinants.**

### Implications for research

- There is an urgent need for more RCTs comparing IRS with ITNs in a number of settings with different epidemiological and socio-cultural characteristics.

- Ideally, such RCTs should have a third arm with a combination of high coverage IRS with high coverage ITNs; each arm should at least have 3 to 5 large-size clusters.

- Participants of all age-groups should be included in such trials.

### Characteristics of included studies (ordered by study ID)

#### Curtis 1998

| Methods | Study design: cluster randomized controlled trial.  
Unit of allocation: village.  
Number of units: 4:4:4  
Length of follow-up: prevalence surveys and passive surveillance: 15 months (3rd & 4th quarter 95 to 4th quarter 96). Incidence surveys: 20 months (April 95 to Dec 1996). Incidence of re-infection was monitored once before the interventions and four times after introduction of intervention (once in each quarter of 1996) by taking weekly blood slides. Cross-sectional surveys were carried out monthly from April 1995 to December 1996. In addition, a passive surveillance system was set up. People feeling sick with fever were encouraged to visit a local research assistant, who was taking a blood slide from them, which were collected weekly.  
Different children were used for each cohort.  
Confidence intervals were not adjusted for clustering. We could retrospectively adjust for the prevalence, but not for the incidence data. |
|---|---|
| Participants | Number of participants:  
Inclusion criteria: incidence: children aged 1 to 6 with cleared pre-existing parasitaemia; prevalence: children aged 1 to 6, passive surveillance: people of all ages feeling sick with fever.  
Exclusion criteria: incidence: children away from home, for having missed the blood slide for more than 1 week; prevalence: children already included in the incidence group, children which were selected in the previous month and children with parasitaemia >4000/µl. Passive surveillance: no specific exclusion criteria mentioned. |
| Interventions | IRS: Microencapsulated lambdacyhalothrin (ICON™) 10%; dosage: 30 mg/m². The wall and roof areas were sprayed with Hudson X-Pert spray pumps. Re-spraying in the villages was carried out seven to eight months after the initial spraying (July to August 1996). The spray coverage was not specifically mentioned but maximal coverage was aimed for.  
ITNs: Lambdacyhalothrin (ICON™); dosage: 10 mg/m² in 2 villages, and 20 mg/m² in the other 2 villages. Retreatment after seven months. The coverage rate was not specifically mentioned. |
| Outcomes | (1) Incidence of re-infection after parasitological clearance with antimalarials  
(2) Incidence rates by passive case detection  
(3) Malaria prevalence  
(4) Haemoglobin levels |
| Notes | Study location: six villages near Muheza, Tanga Region and six villages near Hale, both in northeast Tanzania  
EIR: estimated to be above 300  
Malaria endemicity: high endemicity with intense perennial transmission |
Transmission season: April to June
Main vector: *Anopheles gambiae*, *Anopheles funestus* and *Anopheles arabiensis*
Material of wall sprayed: Mud
Insecticide resistance: None (bioassay test showed mortality of 80-100%)

### Methods

**Study design:** cluster randomized controlled trial.

**Baseline:**
- Unit of allocation: village.
- Number of units: 15:15:15.
- Length of follow-up: two weeks (16th to 30th September 1996).
- Mass surveys in September 1996 (peak transmission season) in 45 villages within the three ecological zones.

**Intervention:**
- Unit of allocation: groups of three nearby villages (but at least one km apart) formed a cluster for random assignment of IRS, ITNs or control. The villages were not evenly distributed within the three ecological zones, 30 in coastal zone, 51 in the plains zone and 45 within the foothill eco zone. The distribution of the randomized villages was equal within the three groups.
- Number of units: 42:42:42.
- Length of follow-up: 18 months.
- Active case detection by home visits twice a week by collecting blood smears from all fever cases. On Sundays, treatment was provided to any sick person calling on the health worker. Monitoring from May 1997 until May 1999 (only data collected until 31.12.1998 were evaluated).
- Cross-sectional mass surveys once per year within the second half of September in 1997 and 1998.
- Drop out rates were 6.0% for IRS, 5.2% for ITN and 5.6% for the control group.
- The retrospective adjustment of incidence confidence intervals was not possible. Neither was the adjustment for prevalence data possible.

### Participants

**Baseline mass survey:**
- Number of participants: 34,292.
- No explicit inclusion/exclusion criteria (all ages).

**Intervention:**
- Number of participants: 93,210 (IRS: 30,989; ITNs: 31,168; control: 31,053).
- No explicit inclusion/exclusion criteria.

### Interventions

The first intervention round took place from 26.5. to 14.6.1997; the second round from 23.5 to 14.6.1998.

**IRS:** deltamethrin 2.5% WP; dosage 20 mg/m². Indoor surfaces of the walls, ceiling, back of cupboards, cots, eaves and cattle sheds were sprayed. Overall spray coverage was 92.2% in 1997 and 95.1% in 1998. In 1997 spray coverage was least in the irrigated plain eco zone (87%) and over 95% in the foothill and coastal eco zone. In 1998, coverage was 95% in all 3 zones. 1.36% and 19.3% of the houses which have received IRS were re-plastered after three and six months, respectively.

**ITNs:** deltamethrin 2.5% SC; dosage 25 mg/m². Overall net coverage of the whole population was very high, with 99.3% in 1997 and 85.4% in 1998, respectively. Overall, 86.8% of the nets were retreated, with the retreatment taking place one year after the distribution (May 1998). In the irrigated plain eco zone, 88.3% were retreated, whereas 95.7% of the nets in the foothill eco zone were retreated. The coverage rate for the coastal area was not mentioned. Only 4% of the nets were washed after nine months of treatment.

### Outcomes

1. Malaria prevalence.
2. Malaria incidence.
Study location: Surat District in Gujarat State, India. 3.7 million population with 54% distributed in 1281 villages. The district is divided into three ecological zones: (1) Foothill: Eastern tract of hilly land, largely deforested, summer hot and dry, maximal rainfall (2) Irrigated plain: cultivation of paddy, sugar cane and plantains, dam which irrigates the entire plain area (3) Coastal: Western coast belt with sandy soil and heavy industries. EIR: <1.

Malaria endemicity: coastal area: hypo-endemic; getting hyperendemic towards eastern hilly tracts.

Transmission season: perennial transmission with peak from June to September.

Main vector: Anopheles culicifacies (zoophilic and endophilic).

Material of wall sprayed: mud or cement.

Insecticide resistance: A. culicifacies is resistant to DDT and malathion, but highly susceptible to deltamethrin, the insecticide used within the study (mortality range for susceptibility tests: 74.4 to 96.5)

Net ownership prior to distribution of nets for the trial was significant higher in the IRS group (16.5%) than in the other two groups (ITN:9.5%; control: 15.5%; Chi² test= 144.69, df=2, P=0.001)

Free of selective reporting? Unclear

Free of other bias? No

Quote: “a high incidence (24.3%) of plastering mud on the walls of houses…” (Bhatia et al. 2004)

Comment: the re-plastering of the walls after spraying most likely reduced the effectiveness of IRS

Mnzava 2001

Methods

Study design: cluster paired randomized controlled trial.
Unit of allocation: geographical blocks (seven pairs of blocks formed on the basis of their average malaria incidence rate (being as similar as possible within each pair); randomization to ITNs or IRS within each pair.
Number of units: 7:7 blocks.
Length of follow-up: 24 months.
Routine active case detection took place monthly by malaria control teams. Blood slides were taken from any member of a household. Passive case detection was done by clinic and hospital staff. Whenever such a case was detected, all household members from where the case came from and including all people living within a 40 km radius of the homestead where the index case occurred, were bled as well. This is the routine procedure for all zones under malaria control in the KwaZulu Natal Province. Calculated incidence rates reflect both passive and active case detection.
Monitoring from January 1997 to December 1998. But results taken only from 1998 because in 1997 spraying had already taken place in ITN clusters.
Drop-outs were not taken into account.
Confidence intervals were not adjusted for clustering. They could not be adjusted retrospectively (due to matching of the pairs).

Participants

IRS: 7649
ITNs: 5450
No inclusion/exclusion criteria mentioned (all ages).
Interventions

IRS: spraying with deltamethrin; dosage 20 mg/m², yearly from September to December, starting in 1996 (prior to the malaria season). The interior walls, ceilings and eaves of all homesteads were sprayed with Hudson X-Pert spray pumps. Spraying coverage is not explicitly mentioned.

ITNs: distribution of permethrin treated nets in January 1997; target dose 200 mg/m². Annual retreatment in January, using deltamethrin (KO-Tab) in 1998 and permethrin in 1999. Over 90% of the nets were retreated. Usage of ITN in 1997 was 98% and 100% in 1998.

Houses in bed net blocks had already been sprayed by the time the nets were distributed in 2007. There was immediately an effort by investigators to re-plaster these houses to cover the insecticide on the walls. In subsequent years, however, house spraying was deliberately withdrawn in blocks with bed nets. Restrict analysis of results to 1998.

Outcomes

(1) Malaria incidence (cases per 1000 person-years)

Notes

Study location: homesteads within Ndumu and Makanis areas of Ingwavuma district in KwaZulu Natal Province. 14,000 inhabitants (predominantly Zulus) served by four clinics and one referral hospital. The area has a long history of IRS. Before 1995, it was sprayed with DDT, thereafter there was a switch to deltamethrin.

EIR: not known but very low because of long-standing malaria control efforts (decades of IRS).

Malaria endemicity: not known (annual malaria incidence of 5%).

Main vector: Anopheles arabiensis (after elimination of A. funestus by IRS).

Material of wall sprayed: mud and cement.

Insecticide resistance: within KwaZulu Natal Province, A. funestus was shown to be resistant to deltamethrin (Hargreaves 2000). However, according to Mnzava 2001 there is no evidence that pyrethroid-resistant A. funestus occurred in the area during the period of the study. For A. arabiensis no resistance was detected in the area.

### Molineaux 1980

| Methods | Study design: controlled before-and-after study  
Unit of allocation: village  
Number of units: 5:6 (control : IRS)  
Every 10 weeks, house-to-house visits were done and a thick film taken. In case of absence a second visit to the home was done.  
Length of follow-up: 36 months.  
Drop-out rate unknown, high levels of migration - 15% to 20% per year. |
|---------|-----------------------------------------------------|
| Participants | IRS: 2310  
Control: 1861  
No explicit inclusion/exclusion criteria mentioned (all ages). |
| Interventions | Propoxur 50% WP; dosage 2 g/m². Three rounds of spraying were applied in 1972, starting on 1 May, 5 July and 6 September, respectively. The intervals between successive rounds in the same village were 61 to 66 days.  
In 1973 spraying was applied in April, June and August and in the southern part in October. The intervals between successive rounds were 56 to 66 days.  
Spray coverage: 74% to 100% (99% on average). |
| Outcomes | (1) Prevalence rate.  
(2) Incidence rate.  
(3) Infant mortality rate |
| Notes | Study location: Garki District in Northern Nigeria.  
EIR at baseline in treated villages: wet season:18 to 132; dry season: 0 (except Sugungum: 13).  
EIR at baseline in untreated villages: wet season:17 to 37; dry season: N/A.  
Malaria endemicity: stable, seasonal.  
Main vector: Anopheles gambiae and Anopheles funestus.  
Material of wall sprayed: clay.  
Insecticide resistance: None mentioned. |
| Risk of bias | |

### Rowland 2000

#### Methods

- **Study design:** cluster-randomized controlled trial.
- **Unit of allocation:** sectors; the study area comprising 60 villages was divided into nine sectors of approximately equal population size and surface area and then each sector was assigned at random to control, Wettable Powder (WP), or suspension concentrate (SC) formulation.
- **Number of units:** 3:3:3 sectors. During analysis the two insecticide groups (WP and SC) were merged into a single group because there was no evidence of difference between them.
- **Length of follow-up:** 2 months before intervention and 7 months after spraying done in June 1997 (one season).
- **Active case detection by home visits every fortnight. Blood slides were taken from any member of a household reporting to having had fever during the previous three days.**
- **Monitoring from April 1997 to January 1998, covering the entire malaria transmission season.**
- **Two cross-sectional surveys were carried out in April-May and September 1997, i.e. before and after the spraying, which was done in June 1997 (one survey within and one survey outside the malaria season, which runs from June to November).**
- **To assess the prevalence rate, blood slides were taken from children of one or two schools selected from sentinel villages in each sector.**
- **Drop-out rates unknown.**
- **Confidence intervals were not adjusted for clustering by authors. We could adjust the incidence and prevalence data retrospectively. See Data collection and analysis for more details.**
- **The rate ratio (RR) of IRS vs no IRS was estimated by a generalized linear model with negative binomial mean and variance functions. This model sowed to best fit the observed cluster-level incidence rates (Generalized Pearson statistics=1.29).**

#### Participants

- **(1) Active case detection:** Number enrolled:18,000 (2000 in each of the 9 sectors).
- **Inclusion criteria into active surveillance group:** any member of a household who reported having had fever during the previous 3 days.
- **Exclusion criteria:** No explicit exclusion (all ages).
- **(2) Cross-sectional surveys:** Inclusion criteria: School children aged 5 to 15 years present in school on the day of the
Interventions
Alpha-cypermethrin WP and SC; dosage 25 mg/m²; living quarters, storage rooms and animals shelters were sprayed with Hudson X-pert spray pumps. Spray coverage: WP: 96%, SC: 97%.

Outcomes
(1) Malaria incidence through active case detection (P. falciparum and P. vivax).
(2) Malaria prevalence through cross-sectional surveys (P. falciparum and P. vivax).

Notes
Study location: 3 Union Councils, covering 180 km² of Sheikhupura District, Punjab Province, approximately 60 km west of Lahore, Pakistan. EIR: < 1
Malaria endemicity: not known (annual incidence of 50 episodes per 1000 person years).
Malaria season: June to November.
Main vector: Anopheles stephensi.
Material of wall sprayed: mud and brick.
Insecticide resistance: no detected resistance, 100% mortality of laboratory-reared and wild-caught A. stephensi.

Sharp 2007

### Methods

Study design: interrupted time series. Only results for zone 1 (enough follow-up time before and after, no spraying interruption) were considered.

- Length of follow-up before intervention: 2 years (1999 to 2000).
- Length of follow-up after intervention: 5 years (2001 to 2005).

Cross-sectional studies were done once per year (in June) within 26 sentinel sites. From a random sample of individuals malaria infections were tested by Rapid Diagnostic Tests (RDTs).

### Participants

First year (1999): all age groups included but data also analysed for age group 2 to 14 years. In subsequent years (2000 to 2005) children between 2 to 14 years were included in surveys.

### Interventions

- Bendiocarb; 400 mg/m², twice per year.
- Spraying was done using Hudson pumps. Spraying personnel were trained in spraying techniques, safety measures and received personal protection equipment.

### Outcomes

(1) Malaria prevalence of P. falciparum

### Notes

- Study location: Maputo Province in Southern Mozambique.
- EIR: > 1 before control activities started.
- Malaria endemicity: stable malaria before control activities started.
- Main vector: *A. arabiensis*; *A. funestus*.
- Material of wall sprayed: Not known.
- Insecticide resistance: None.

<td>Quote 1: “IRS was interrupted from 2001 to 2002 because of resource constraints, but resumed in the second half of 2003”. Comment: Due to the interruption of IRS, it is likely that the effect of the spraying will be underestimated. Quote 2: “All age categories were sampled in December 1999, and subsequent surveys were confined to children two to 14 years of age”. Comment: In a malaria endemic area, the</td>
</tr>
</tbody>
</table>
risk of infection is higher for children than for adults. Therefore the prevalence might be affected when comparing the year with all age groups compared to the years with children only. However, looking at the difference in the prevalence rates of the year with all age-groups surveyed versus subsequent years, this effect seems negligible.

**CONTRIBUTIONS OF AUTHORS**

BP: reference identification, screening, retrieval of papers for eligibility, data extraction, analysis of data, main writing.

FT: preliminary reference identification, screening retrieved papers for eligibility, contribution to writing.

CL: initial concept, organization of reference searching, second data extraction, contribution to writing and supervision.

BS: Initial concept, technical inputs in technical matters.

Sadly, BS passed away during the initial phase of the review. His experience, drive and good nature are sorely missed.

**DECLARATIONS OF INTEREST**

None known.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

We planned to convert the outcomes for anaemia presented as g/dL into packed cell volume with a standard factor of 1:3. But Carneiro 2007 showed that this conversion is not always accurate and since we only had one trial providing haemoglobin measures, we presented them as they were presented within the paper (in g/dL).

We did not find individually randomized RCTs in the frame of this review. However, the methods of extracting data and analysing such trials would follow the methods outlined in the protocol.

We did not do a sensitivity analysis due to the small number of trials. However, the methods published in the protocol will be followed, if appropriate, in future updates of this review.

We only found one eligible ITS for our review and presented its results as shown in the paper. If further trials will be included in future updates we will analyse them as published in the protocol.

Methodological quality was assessed using the Cochrane Collaboration's risk of bias tool (Higgins 2008).

No summary of the major debates and findings of other reviews on DDT was included in the discussion as none of our included studies used DDT as insecticide.

There was a change in the authorship. BP replaced FT as first author because she took the lead in this work.
